Running title:

Bone marrow edema minimalist running shoes
Abstract

Purpose: Minimalist running shoes are becoming a more popular choice for runners in the past few years. However, there is little conclusive evidence about the advantages or disadvantages of running in these shoes. While performance benefits may exist, injury may also occur from the added stress of running without the benefit of cushioning under the foot. Bone marrow edema can be a manifestation of added stress on the foot. This study measured bone marrow edema in runners’ feet before and after a 10 week period of transitioning from traditional to minimalist running shoes.

Methods: Thirty-six experienced, recreational runners underwent MRIs before and after a 10 week period. Seventeen subjects were in the control group (ran in their traditional shoes only for 10 weeks), while the other 19 were in the experimental group (gradually transitioned to VibramFiveFinger running shoes over 10 weeks). The severity of the bone marrow edema was scored on a range of 0-4 (0 = no bone marrow edema, 3 = edema in more than 50% of the length of the bone). A score of 4 represented a stress fracture.

Results: Pre-training MRI scores were not statistically different between the groups. The post-training MRI scores showed that more subjects in the Vibram group (10 of 19) showed increases in bone marrow edema in at least one bone after the 10 weeks of running than in the control group (p = .009).

Conclusion: Runners interested in transitioning to minimalist running shoes, such as Vibram FiveFingers should transition very slowly and gradually in order to avoid potential stress injury in the foot.

Key words: stress injury, runners, footwear, MRI
INTRODUCTION

Prior to the 1970s, before the development of the modern, traditional running shoe, individuals ran either barefooted or in minimal footwear, such as modified sandals(13, 17). Recently, it has been suggested that running in traditional running shoes, which usually have a cushioned sole, may result in reduced performance (23), increased risk of injury (23), limitation of proprioception (13), and increased ground collision forces in rear-foot strikers (13). For these reasons, there has been a recent resurgence in the running community of running barefoot and/or in minimalist shoes(4). Consequently, shoe manufacturers are continually releasing new models of minimalist shoes to accommodate this growing interest. Concurrently, research is being conducted to assess potential benefits of running in minimalist shoes. Research examining barefoot running has reported that habitual barefoot endurance runners experience fewer running-related injuries than shod runners, though the conditions within the Haitian population measured may influence those results (18). The American Podiatric Medical Association (APMA) Position Statement on barefoot running states that it“has been touted as improving strength and balance, while promoting a more natural running style. However, risks of barefoot running include a lack of protection—which may lead to injuries such as puncture wounds and increased stress on the lower extremities. Currently, inconclusive scientific research has been conducted regarding the benefits and/or risks of barefoot running”(1). Minimalist running shoes are designed to allow runners to employ the same mechanics as in barefoot running without the risk of injury due to contact between the bare foot and the ground. Due to the increasing popularity of minimalist running shoes, it is imperative that researchers, clinicians, and runners understand the potential risks present when transitioning from running in traditional running shoes to minimalist running shoes.
One of the primary concerns of barefoot/minimalist running is that although foot musculature may be strengthened, injury may result from the added stress placed on the bones in the foot, especially throughout the adaptation period when runners transition from traditional running shoes(8). This is of particular concern, considering the incidence of stress syndrome or fractures in runners, even in traditional shoes(14). Similarly, runners may be at risk for developing tendinitis and plantar fasciitis during this critical time frame. It has been suggested that most runners will transition from a rear-foot strike to a mid-foot or fore-foot strike when running barefoot or in minimalist running shoes(5, 7, 13, 20). The lack of cushioning under the foot during this transition may place the runner at greater risk for stress injury at the mid- or fore-foot. If a runner does not adapt from a rear-foot strike pattern, the large forces (1.5 – 3 times body weight) associated with foot strike during running will be transmitted directly to the heel, without the assistance of the shock-absorbing sole of the running shoe(13). This increases the potential for injury to the bony and soft tissue structures of the heel and lower extremity. Anecdotally, clinicians have reported an increase in foot injuries in runners while transitioning to minimalist shoes. Although there is a lack of conclusive evidence in scientific literature, Giuliani et al. report two cases of stress fractures in runners as they transitioned to minimalist running shoes(8).

A very sensitive measurement tool must be used to determine risk of stress injury in the foot due to transitioning to minimalist running shoes. Although some overuse injuries, such as stress fractures and callus, can be seen on x-rays, a more sensitive measurement tool is necessary in order to detect early changes that may indicate the development of a stress injury(19). Magnetic Resonance Imaging (MRI) makes it possible to detect bone stress injuries of the ankle and foot weeks before radiographs would demonstrate osseous abnormalities(6, 11, 19). Early
changes of stress injury to bone are characterized by reabsorption and replacement of bone, marked by local hyperemia and edema, that may be missed in early radiographic imaging but can be captured by MRI(6, 16, 19). An additional advantage of MRI is the ability to grade and classify lesions(11). Grading is performed by assessing the presence of endosteal marrow edema, periosteal edema, muscle edema, existence of a fracture line and callus formation. Nivaet al. found that early detection and grading of bone stress injuries was not only possible using MRI, but also essential in early and appropriate injury management (16). It has been suggested that MRI should be used as the gold standard in the assessment of stress injuries of bone(11). A previous study showed that bone marrow edema changes in the foot were detectable with MRI after just 1 week of running (21).

There has been evidence of MRI detecting stress reactions in athletes and military recruits who are asymptomatic(3, 10). These asymptomatic stress reactions were low grade bone response (less than 3 on a 0-4 point scale), while a score of 4 (stress fracture) was associated with symptoms (3, 10). Despite this, MRI is still the one of the best objective tools available to measure the reaction of bones and tendons to stress.

The purpose of this study was to assess bone and soft tissue changes in experienced, recreational runners during a 10-week transitional period from traditional to minimalist running shoes. We hypothesized that the prevalence of bone and soft tissue changes would be greater in the runners who transitioned to minimalist shoes compared to those runners who continued running in traditional running shoes throughout the same time period.
METHODS

Thirty-six experienced, recreational runners (21 male, 15 female) participated in this study (mean age 26.5 ± 6.6 years; height 175.2 ± 10.1cm; mass 70.5 ± 11.8kg). To qualify for participation, runners had to complete an average of 15-30 miles/week for the 6 months prior to the start of the study. Subjects were excluded if they had ever run in Vibrams prior to the study or if they had suffered a lower body injury that kept them from running at least 3 days/week at any time in the previous 6 months. All subjects signed institutionally approved informed consent forms, completed a medical/injury history questionnaire documenting that they were pain-free prior to participation in the study. Subjects were also screened by a physician and received a pre-participation MRI of the foot, ensuring that there were no pre-existing injuries.

Forty-three subjects began this study. Subjects were randomly assigned to the minimalist (Vibram) or control group. In order to avoid the chances of a large discrepancy between the number of males and females in either group, male subjects drew group assignments out of one bag, while females drew out of another bag. In each bag were equal numbers of Vibram and Control assignments. Seven subjects did not complete the study for a variety of reasons - three subjects completed the training, but did not return for a follow-up MRI; two subjects were injured over the course of the 10 weeks, unrelated to participation in this study; another two subjects did not respond to contact after their initial MRIs.

Both groups were encouraged to continue their typical running regimen throughout the 10-week period following the initial MRI. The Vibram group transitioned from traditional running shoes to VibramFiveFinger™(VFF) running shoes gradually over that time by replacing some mileage in traditional shoes each week with mileage in the VFF. The transition protocol used in this study was modeled from suggestions for transitioning to VFF published on the
Vibram FiveFingers website in January 2011 (the suggestions on the website have changed since then)(22).

Participants in the Vibram group were instructed to run one short (1-2 mile) run in the VFF during their first week of training. During the next 2 weeks, they were to run in the VFF for one additional short (1-2 mile) run each week, thus during week three, they would run at least 3 miles in the VFF. After the third week of running, subjects were advised to add mileage in the VFF as they felt comfortable, with the goal of replacing one short run per week in traditional shoes with a short run in the VFF. The flexibility of this protocol was chosen to allow the subjects to transition as they would if they had just bought the shoes and were not participating in a research study. Although the lack of control over how much each subject ran in the Vibrams each day is a limitation to scientific research, this more accurately simulated a real-life situation. In order to understand how each subject transitioned, all subjects kept a training log to document the length of each run, time spent running, footwear worn, and any foot/leg pain. After 10 weeks of running, all subjects reported back for a follow-up MRI. MRIs were taken in the morning and subjects were instructed not to run that day prior to their appointment.

MR Images were taken using a Hitachi 0.7 TAaltaire “open” magnet. Both feet were placed in a head coil and then placed in an iso-center position within the magnet. The field of view included the entire foot, including the distal tibia and fibula. Axial (long-axis) and sagittal T2-weighted fast short tau inversion recovery (FIR) images and axial T1 weighted spin echo images were obtained. Axial T1 weighted images were performed with a 23 cm field of view, 256 x 192 matrix, 5 mm thickness and 2 mm spacing, TR 455 and TE 18. Axial FIR images were performed with a 23 cm field of view, 256 x 176 matrix, 5 mm thickness with 2 mm spacing, TR
Sagittal FIR images were performed with a 23 cm field of view, 256 x 176 matrix, 5 mm thickness and 1 mm spacing, TR 3690, TE 12, TI 110.

Bone marrow edema was scored according to a system based on the method used by Lazzarini et al., as described in Table 1A(12). The Achilles tendon, dorsi-flexor, plantar-flexor, and peroneal tendons, and plantar fascia were scored with the scoring system shown in Table 1B. Images were independently reviewed using a Dominator DR PACS workstation by 3 musculoskeletal trained, board certified radiologists. The radiologists were blinded to control and minimalist runners. Radiologists had pre- and post-10-week training images for comparison. Consensus was considered achieved when 2 of the 3 radiologists were in agreement with both the pre- and post-scores. If all 3 radiologists reported different scores, they were shown the images again and asked to re-score them. They were blinded to the other radiologists’ scores. In all cases, the re-scoring resulted in consensus between the radiologists the first time they re-analyzed the images. In order to quantify intra-rater reliability of the radiologists, each doctor re-scored 20 images. The initial scores of the 20 images ranged from 0-4. The average ICC for the doctors was .93 ± .02.

Data were analyzed using Fisher’s Exact test in SAS (SAS Institute, Inc, Cary, NC). Subjects were grouped by severity of post-test MRI findings across all the structures in the foot. Comparisons were made between subjects who had scores of 0 or 1 and those that had at least one structure (on either foot) that showed a score of 2, 3, or 4 in their post-test images. Data was then compared for subjects in the minimalist group to subjects in the control group. Pre-test data was also compared to ensure that there were no differences prior to the start of the study.
RESULTS

The pre-training MRI scores were not statistically different for the two groups (p = 1.00 for bone, p = .191 for soft tissue). The post-training MRI scores showed that more subjects in the Vibram group showed increases in bone marrow edema in at least one bone after the 10 weeks of running than in the control group (see Table 2; p = .009). The groups were not significantly different with respect to post-training MRI scores in the soft tissue (p = .444). Only 1 subject had a post-test tendon score of 2 in the plantar fascia. The pre-test tendon score for that subject’s plantar fascia was also 2. No subjects had a tendon score of 3 during pre- or post-test measurements.

Table 3 shows the magnitude of the MES during the post-training MRI for the most commonly reported locations of bone injury in the foot (12, 15, 24). These numbers represent the total number of structures showing bone marrow edema changes in all feet. These results show a higher incidence of intense signal sub-fracture bone marrow edema as designated by an MES of 3 (stress injury) in the Vibram group (3 out of 16 subjects in the Vibram group compared to 0 out of 20 subjects in the control group). However, a particular individual may have had more than one involved bone. For example, one individual had bilateral increased signal to an MES of 3 in the 2nd metatarsal and unilateral increased signal in the 3rd metatarsal. Another subject showed bilateral increased signal in the talus, while another individual only had increased signal in one of their 3rd metatarsals. Increased signal intensity in the feet of the Vibram group to an MES of 2 was found in 8 of the 16 of participants. Including the two subjects who suffered from stress fractures, 11 of the 16 subjects in the Vibram group were classified as “injured” (at least one structure with an MES ≥ 2 ) at the end of the study.
DISCUSSION

The results of this study showed that increases in bone marrow edema are more common in subjects who were transitioning to the VFF. Bone marrow edema changes are indicative of added stress and have been seen in sedentary subjects who ran for only 7 days in a row in traditional running shoes(21). In the current study, few subjects in the control group showed any change (post-test MES = 1) in bone marrow edema over the 10 weeks of participation in this study, and only one had a post-test MES of 2. This, combined with the findings of Trappeniers et al., suggests that our subjects were conditioned enough through their previous running experience that it was not the running, but the added stress of transitioning to VFF that contributed to the higher incidence of bone marrow edema in the Vibram group (21).

It is important to note that for data analysis, subjects with an MES of 0 or 1 were grouped together because a 1 does not necessarily constitute an injury. An MES of 1 could very well be the product of the physiologic phenomenon of osseous remodeling due to stress which is essential to the normal development and maintenance of bone(2). With appropriate application of stress, the remodeling process results in a stronger bone structure – which is visible on the MRI by low levels of bone marrow edema. However, if continued stress occurs more frequently than the remodeling, this can result in an imbalance that renders cortical and trabecular bone weakened(19). Persistent stress could further lead to bone fatigue, injury or fracture; represented by increasing amounts of bone marrow edema, respectively. Edema in 25-50% of the bone (MES = 2) is considered a stress reaction and a potential cause for concern. At this point, running should be limited and cross-training should be encouraged. Edema in more than 50% of the bone length (MES = 3) is considered a stress injury, at which point participation in running should cease. Out of the 19 Vibram group participants, 9 had edema grades of 0 and 1 (non-
injured) and 10 had edema grades of 2, 3 or 4 (injured). This is significantly higher compared to the control group, where 16 subjects were considered non-injured and only 1 was considered injured. Although most runners will not know about the presence or degree of bone marrow edema, our results suggest that if a runner transitioning to VFF feels pain, they should modify their running regimen.

The location of the fractures and bone marrow edema observed in our study are comparable to other studies (12, 15, 24). Two individuals (out of 19) in the Vibram group experienced stress fractures as indicated by an MES score of 4, while the shod running group showed no fractures. One individual in the Vibram group suffered a calcaneal fracture, while another had a 2nd metatarsal fracture. Tarsal and metatarsal stress fractures have been reported by other researchers investigating athletes and military recruits(12, 24). In a study of 320 athletes with stress fractures, researchers found that tarsal fractures (25.3%) were the 2nd most commonly fractured bones after the tibia (49.1%) while metatarsal fractures (8.8%) were 3rd most common(15). In a review of studies investigating stress fracture incidence, the occurrence of stress fractures in athletes ranged from 1.4% to 18.3% in tarsal bones, while stress fractures in the metatarsals ranged from 8% to 24.6%(24). Some studies only reported stress fractures in the foot, which ranged from 28% to 33.8%(24). The tibia appears to be the most likely of the lower extremity bones to experience stress fractures in an athletic population, often accounting for 40 to 50% of stress fractures(24). None of the participants in our study showed bone marrow edema in the distal tibia during the 10 weeks of training. Jones et al. stated that in athletic populations, incidence of stress fractures vary depending on the sports, although the highest generally occurs in female runners(9). Of the 11 runners who had MES scores of 2 or greater in this study, 8 were
female. This may suggest that female runners need to focus on a slower transition to VFF running shoes even more than male runners.

Participants in this study were required to keep a training log to document their running. Although the original intention of the study design was for all subjects to have completely transitioned to VFF running shoes by the end of the 10 weeks of training, this did not happen for the majority of subjects. Mileage data from the final week of each subject’s training log indicates that only 1 subject ran exclusively in the VFF during the last week of entries into the training log. It should be noted that some subjects stopped logging their runs prior to the 10th week of training and 4 of the 19 Vibram subjects did not document their training at all, though they did participate in both pre- and post- testing and therefore, were included in the statistical analysis in this study. This lack of documentation presents a limitation to this study.

The subject who was running exclusively in the VFF ran 16-17 miles during the last 2 weeks of the study. During the last week, she reported some pain and did change back to traditional shoes for 3 miles of one run. Her only non-zero MES scores were Left Talus (MES = 1) and Right Talus (MES = 2).

The data reported from the training log supports the statement that the rate of transition is an important aspect to consider when runners start wearing VFF running shoes. Figure 1 shows mileage data from the control and Vibram sub-groups (injured and non-injured) for one week of the study. The week chosen was the week during which the subject ran the most miles in their respective shoe. It should be emphasized that for the Vibram sub-groups, these data were not from the week during which the subject ran their total peak mileage (traditional plus VFF mileage), but rather maximum mileage in the VFF only.
Within the Vibram sub-groups, subjects ran their maximum weekly mileage in VFF during a range of weeks (weeks 1 – 9). Seven subjects ran their maximum mileage in VFF prior to or during week 4. This early peak shows that subjects chose not to increase their weekly mileage during the second half of the 10 week study - possibly due to discomfort, injury, or other difficulty running in the VFF.

Although we don’t know why many runners ran their maximum mileage early in the study, perhaps perceived pain is a possible explanation. The perceived pain scale scores recorded on the training logs were highly variable between runners. For example, the two individuals that suffered stress fractures reported perceived pain scores of 2 and 4 out of 10 during running, while some other runners without injury reported higher pain levels. Again, it should be noted that studies have shown that MRI findings can be positive for stress reactions in asymptomatic individuals(3, 10). Therefore, it is possible that a runner that is transitioning to minimalist running shoes may have a stress reaction, but be asymptomatic. Runners who had the highest level of stress injury consistently reported symptoms(10), supporting the notion that if a runner is feeling consistent pain affecting their ability to run, a modification should be made to their training protocol.

It is also valuable to note that although the Vibram sub-groups ran the same mileage in the VFF during the peak week, the non-injured group ran fewer miles in traditional running shoes during that week. This suggests that it may not be only VFF mileage that contributes to injury as much as the total stress on the foot with the added stress of running in the VFF.
CONCLUSION

Although many runners are making the change to Vibram running shoes, there is currently a lack of agreement on the advantages or disadvantages of this change. This study examined the potential for stress injury by measuring the presence of bone marrow edema and soft tissue damage in the foot after runners transitioned to Vibram FiveFingers™ shoes throughout a 10 week transition period. The Vibram group had a significantly greater incidence of bone marrow edema after the training period, while neither group showed any soft tissue changes. Thus, to minimize the risk of bone stress injury, runners who want to run in VFF should transition over a longer duration than 10 weeks and at a lower intensity (miles per week) than the subjects in this study.
